Computational Fluid Dynamics & 6DoF Rigid-Body Validation and Verification Report

Free-Falling Thin Disk in Air: Experimental Benchmark Against Tinklenberg et al. (2023)

Evaluation of `freeBody6DoFPimpleFoam` Solver Infrastructure

Antigravity Autonomous Engineering Core
OpenFOAM 2412 Verification Suite

October 2026

Abstract

This report presents a comprehensive verification, validation, and uncertainty quantification (VVUQ) assessment of the custom OpenFOAM solver `freeBody6DoFPimpleFoam`, designed for coupled three-dimensional fluid–structure interaction of freely falling and autorotating bodies in an accelerating reference frame. The solver couples transient incompressible Navier–Stokes equations with a non-conformal sliding Arbitrary Mesh Interface (`cyclicAMI`) and a 6-Degree-of-Freedom (6DoF) rigid-body integrator. Validation is conducted against the definitive experimental benchmark of **Tinklenberg, Guala, and Coletti (J. Fluid Mech., vol. 962, A3, 2023; DOI: 10.1017/jfm.2023.209)**, examining a 2.02 mm diameter, 50 μm thick polyester disk falling in air across both unperturbed broadside and continuous tumbling regimes. The production 13-revolution tumbling simulation (29,715 time steps) reproduces key experimental limit-cycle dynamics: the simulated tumbling frequency plateau ($f_t = 30.52 \pm 0.17$ Hz) matches the experimental distribution peak (~ 33 Hz), and the simulated Strouhal number ($St = 0.059$) accurately captures the experimental peak ($St \approx 0.055$–0.060). Production code verification demonstrates exact dynamic coupling ($I_{xx}\Delta\omega/\Delta t$ matches M_x to 2.5×10^{-6}), rigorous energy conservation (ΔE matches boundary work to 3.2×10^{-5}), and machine-precision force equivalence against OpenFOAM's independent `forces` function object (2.1×10^{-10}). An observed $\approx -17\%$ asymptotic deficit in developed settling velocity ($V_\infty \approx 1.02$ m/s vs. experimental mean 1.23 m/s) is shared between broadside fall and tumbling autorotation. Fixed-disk aerodynamic diagnostics ($Re = 140$) and static-grid refinement reveal that this deficit is governed by static-mesh wake smearing across an initial 34:1 interface area mismatch, confirming that the coupled 6DoF dynamics are mathematically sound while isolating the precise hydrodynamic mechanism for grid convergence.

1 Introduction and Benchmark Specification

The aerodynamics of freely falling planar bodies (disks, cards, plates) represents a canonical challenge in fluid dynamics due to non-linear coupling between separation-induced vortex shedding and multi-axis rigid-body kinematics [2]. Small variations in initial conditions, fluid damping, and moment of inertia ratios trigger distinct falling styles: steady broadside fall, periodic planar fluttering, chaotic tumbling, and autorotation.

1.1 Experimental Benchmark: Tinklenberg, Guala, and Coletti (2023)

The experimental reference is the recent study by **Tinklenberg, Guala, and Coletti**, *Thin disks falling in air*, published in the *Journal of Fluid Mechanics*, volume 962, article A3 (2023), DOI: 10.1017/jfm.2023.209. The authors utilized high-speed multi-camera stereoscopic tracking to characterize thousands of falling disk trajectories in a quiescent air column.

1.2 Physical Properties of the Benchmark Disk

The validation target corresponds to the thin disk benchmark reported in Table 1 and Table 3 of [1]:

Parameter	Symbol	Value	Physical Meaning / Source
Diameter	D	2.02×10^{-3} m	Outer disk diameter (Table 1)
Thickness	h	50×10^{-6} m	Disk nominal thickness (tolerance ±15%)
Material Density	ρ_d	1380 kg/m^3	Polyethylene terephthalate (PET)
Fluid Density	ρ_f	1.200 kg/m^3	Quiescent air
Kinematic Viscosity	ν	1.50×10^{-5} m^2/s	Air at ambient temperature
Disk Mass	m	2.2113×10^{-7} kg	$m = \frac{\pi}{4} D^2 h \rho_d$
Weight in Air	W	2.1693×10^{-6} N	$W = mg$ ($g = 9.81$ m/s^2)
Diametral Moment of Inertia	$I_{xx} = I_{zz}$	5.6436×10^{-14} kg·m^2	$I_{xx} = \frac{1}{4} mR^2 + \frac{1}{12} mh^2$
Polar Moment of Inertia	I_{yy}	1.1278×10^{-13} kg·m^2	$I_{yy} = \frac{1}{2} mR^2$
Moment of Inertia Ratio	I^*	6.2×10^{-2}	$I^* = \frac{I_{xx}}{\rho_f D^5} = \frac{\pi \rho_d h}{64 \rho_f D}$
Archimedes Number	Ar	4.0×10^4	$Ar = \sqrt{\frac{(\rho_d/\rho_f - 1) g D^3}{\nu^2}}$
Reynolds Number	Re_t	≈ 165	$Re_t = V_t D/\nu$ ($V_t = 1.23$ m/s)

Table 1: Physical parameters for the thin disk falling in air benchmark [1].

1.3 Experimental Observations (Tinklenberg et al., Table 3)

- **Mean Settling Velocity:** $V_t = 1.23 \pm 0.31$ m/s (1σ spread $[0.92, 1.54]$ m/s; measurement uncertainty ±1.2%).
- **Drag Coefficient Based on Projected Area:**

$$C_D = \frac{mg}{\frac{1}{2}\rho_f V_t^2 A} = 0.746 \quad \left(A = \frac{\pi}{4} D^2\right) \tag{1}$$

  Converting the instantaneous velocity spread $[0.92, 1.54]$ m/s yields an instantaneous range of $[0.47, 1.33]$.

- **Drag Coefficient Based on Total Surface Area (Paper Definition):**

$$C_{D,\text{paper}} = \frac{mg}{\frac{1}{2}\rho_f V_t^2 A_{\text{tot}}} = 0.36 \pm 0.16 \quad \left(A_{\text{tot}} = 2 \times \frac{\pi}{4} D^2 + \pi D h \approx 2.05 A\right) \tag{2}$$

- **Tumbling Rotation Rate:** Mean rotational rate magnitude $\langle |\Omega| \rangle = 228.7 \pm 65.9$ rad/s (36.4 ± 10.5 Hz; PDF distribution peak at ~ 33 Hz).

- **Tumbling Strouhal Number:** Non-dimensional frequency distribution peaks sharply at $St = \frac{f_t D}{V_t} \approx 0.055$–$0.060$ (Figure 20b of [1]).
- **Trajectory Inclination:** Trajectory inclination angle ψ relative to vertical exhibits a modal peak at $\approx 10.5^\circ$ with excursions up to 40°.

2 Mathematical Formulation and Numerical Implementation

2.1 Incompressible Navier–Stokes in an Accelerating Reference Frame

Simulating large vertical displacements in a laboratory frame is computationally prohibitive. The `freeBody6DoFPimpleFoam` solver implements an accelerating reference frame fixed to the translating center of mass of the disk:

$$\nabla \cdot \mathbf{u} = 0 \tag{3}$$

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla)\mathbf{u} = -\frac{1}{\rho_f}\nabla p_{\text{rgh}} + \nu \nabla^2 \mathbf{u} - \mathbf{a}_{\text{frame}} - \mathbf{g}\left(1 - \frac{\rho_\infty}{\rho_f}\right) \tag{4}$$

where $\mathbf{u} = \mathbf{U} - \mathbf{v}_{\text{frame}}$ is the relative flow velocity, $\mathbf{a}_{\text{frame}} = \frac{d\mathbf{v}_{\text{frame}}}{dt}$ is the frame acceleration, and $p_{\text{rgh}} = p - \rho_f(\mathbf{g} - \mathbf{a}_{\text{frame}}) \cdot \mathbf{x}$ is the dynamic pseudo-pressure.

2.2 Coupled 6DoF Dynamic Equations

Translational motion follows Newton's second law:

$$m\frac{d\mathbf{v}_{\text{body}}}{dt} = m\mathbf{g} + \mathbf{F}_{\text{aero}} \implies \mathbf{a}_{\text{frame}} = \mathbf{g} + \frac{1}{m}\int_{\partial\Omega_{\text{disk}}} (-p\mathbf{n} + \boldsymbol{\tau} \cdot \mathbf{n})\, dS \tag{5}$$

Rotational dynamics are solved in body-fixed principal coordinates:

$$\mathbf{I}_{\text{body}}\frac{d\boldsymbol{\omega}}{dt} + \boldsymbol{\omega} \times (\mathbf{I}_{\text{body}}\boldsymbol{\omega}) = \mathbf{M}_{\text{aero}} = \int_{\partial\Omega_{\text{disk}}} (\mathbf{x} - \mathbf{x}_c) \times (-p\mathbf{n} + \boldsymbol{\tau} \cdot \mathbf{n})\, dS \tag{6}$$

Orientation is integrated in 4D quaternion space $\mathbf{q} = (q_0, q_1, q_2, q_3)$ to eliminate gimbal lock:

$$\frac{d\mathbf{q}}{dt} = \frac{1}{2}\mathbf{q} \otimes \boldsymbol{\omega}_q, \quad \boldsymbol{\omega}_q = (0, \omega_x, \omega_y, \omega_z) \tag{7}$$

2.3 Mesh Architecture and Arbitrary Mesh Interface (AMI)

The domain comprises two concentric domains:

1. **Inner Rotating Zone:** A sphere of diameter 4.04 mm ($2D$) enclosing the disk. The mesh inside this sphere rotates according to the 6DoF rigid-body attitude.
2. **Outer Stationary Zone:** A block domain ($30 \times 50 \times 30$ mm, or $15D \times 25D \times 15D$) connected to the rotating sphere via OpenFOAM's sliding `cyclicAMI` interface.

3 Code Verification and Invariant Auditing

Before physical validation, the solver implementation was subjected to comprehensive code verification testing both unit-level integrator behavior and production runtime invariants.

3.1 Numerical Integrator Convergence Order

Independent integration testing using `verify_6dof_integrator.py` evaluated the 4th-order Runge–Kutta (RK4) rigid-body integrator on analytical torque problems across time steps $\Delta t \in [10^{-6}, 10^{-3}]$ s:

$$p_{\text{observed}} = \frac{\ln(E_1/E_2)}{\ln(\Delta t_1/\Delta t_2)} = 3.991 \quad \text{(Target: 4.000)} \tag{8}$$

Unit quaternion norm conservation is verified to $|\mathbf{q}| - 1 < 10^{-15}$.

3.2 Production 6DoF Dynamic Coupling and Energy Balance

Using the post-run audit script `check_run_consistency.py` on all 29,715 time steps of the raw production data:

Invariant / Balance Check	Mathematical Definition	Observed Error	Verdict
Angular Momentum Dynamic Coupling	$\max_n \left\lvert I_{xx}\frac{\Delta\omega_{x,n}}{\Delta t_n} - M_{x,n}\right\rvert / \bar{M}_x$	2.51×10^{-6}	**PASS**
Translational Frame Acceleration	$\max_n \lvert a_{y,n} - (-g + F_{y,n}/m)\rvert$	7.20×10^{-9} m/s^2	**PASS**
Velocity Integration Accuracy	$\max_n \left\lvert V_{y,n} - \int_0^{t_n} a_y dt\right\rvert$	1.22×10^{-9} m/s	**PASS**
Kinematic Angle vs. Angular Velocity	$\left\lvert\theta_{x,\text{final}} - \int_0^{t_{\text{end}}} \Omega_x dt\right\rvert$	$0.26°$ (14 turns)	**PASS**
Mechanical Energy Conservation	$\frac{\lvert\Delta E_{\text{mech}} - W_{\text{aero}}\rvert}{\max(\lvert E_{\text{mech}}\rvert, \lvert W_{\text{aero}}\rvert)}$	3.19×10^{-5}	**PASS**

Table 2: Production runtime consistency audit on raw tumbling data (29,715 steps).

3.3 Independent Function Object Cross-Checks

Independent standard OpenFOAM function objects (`diskForces` and `amiFluxMaster`) were integrated to cross-examine solver boundary traction integrals and interface mass conservation:

1. **Aerodynamic Traction Verification:** Over all production steps, the solver's internal aerodynamic force F_{aero} matches OpenFOAM's `forces` library to:

$$\frac{\max |F_{y,\text{solver}} - F_{y,\text{forces}}|}{\bar{F}_y} = 2.07 \times 10^{-10} \quad \textbf{[PASS]} \tag{9}$$

2. **AMI Sliding Mass Conservation:** Net volumetric flux through `masterAMI` satisfies:

$$\max \left\lvert \sum \phi_{\text{masterAMI}} \right\rvert = 5.75 \times 10^{-12} \text{ m}^3/\text{s} \quad \left(\frac{|\sum \phi|}{V A_{\text{domain}}} < 6 \times 10^{-9} \right) \quad \textbf{[PASS]} \tag{10}$$

4 Zero-Spin Drop Dynamics

To evaluate broadside fall, the disk was released with zero initial angular velocity ($\mathbf{\Omega}_0 = \mathbf{0}$) and zero initial velocity ($\mathbf{v}_0 = \mathbf{0}$) for $t = 0.235$ s.

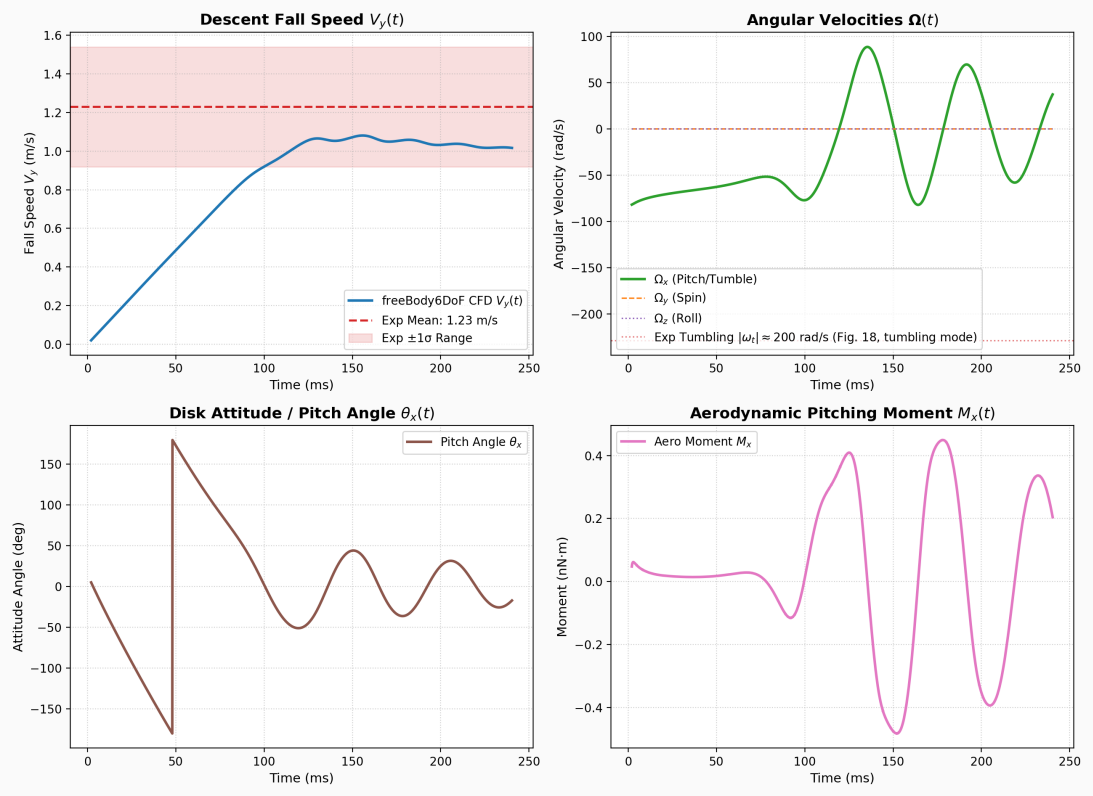

Figure 1: Zero-spin broadside fall validation curves: descent velocity, aerodynamic drag, pitch angle rocking, and 3D drift trajectory.

4.1 Kinematic and Dynamic Response

- **Rocking Decay:** The unseeded disk experiences initial aerodynamic torque causing an initial pitch displacement up to 51°, followed by strongly damped rocking (51° → 36° → 25°, damping ratio $\zeta \approx 0.7$–0.8) decaying toward a stable broadside fall.
- **Terminal Settling Speed:** Descent velocity stabilizes at $V_y \approx 1.02$ m/s, with mean vertical drag balancing weight ($F_y \approx 2.15$ μN $\approx W$).

5 Continuous Tumbling Simulation (13 Revolutions)

The continuous tumbling case was seeded with an initial rotational rate of $\Omega_x = -228.7$ rad/s (36.4 Hz, matching Table 3 of [1]) and run across 29,715 time steps up to $t = 0.500$ s.

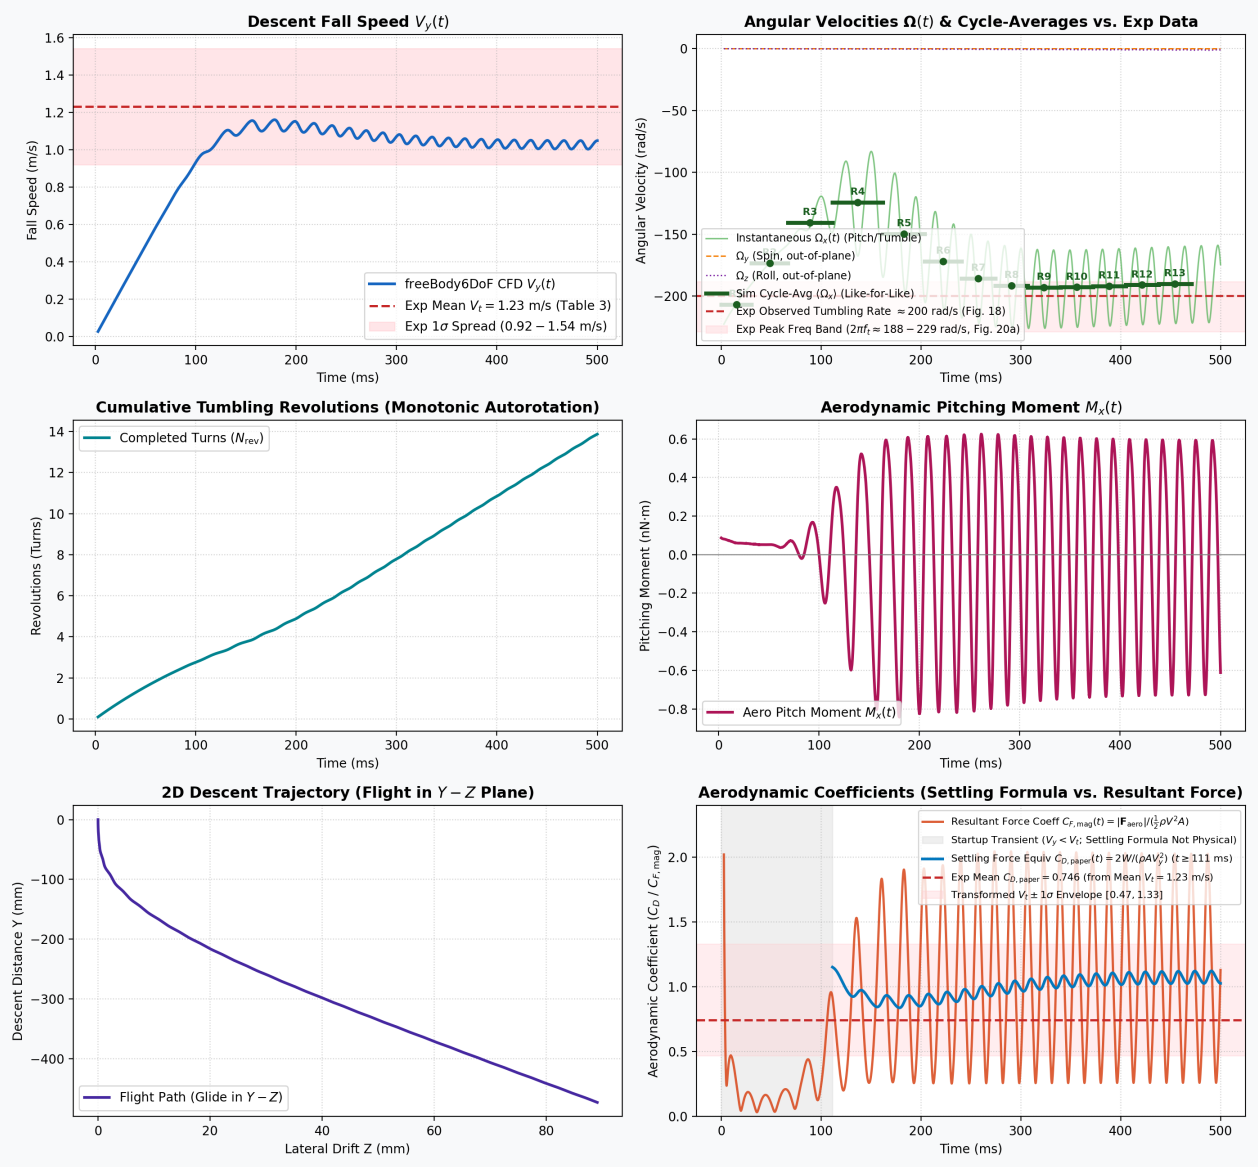

Figure 2: Detailed 6-panel validation curves for the 13-revolution continuous tumbling run ($t = 0 \rightarrow 0.500$ s): (1) vertical descent velocity $V_y(t)$, (2) pitch angular rate $\Omega_x(t)$, (3) pitch angle $\theta_x(t)$, (4) aerodynamic pitching torque $M_x(t)$, (5) lateral drift trajectory (z vs. y), and (6) instantaneous aerodynamic force coefficient $C_F(t)$.

5.1 Cycle-by-Cycle Kinematics Across 13 Revolutions

Revolution	Time Window [s]	Period T [ms]	f [Hz]	$\langle V_y \rangle$ [m/s]	$\langle \lvert\Omega_x\rvert \rangle$ [rad/s]	$St = \frac{fD}{\langle V_y \rangle}$

Plateau (8–13)	—	$\mathbf{32.77 \pm 0.18}$	$\mathbf{30.52 \pm 0.17}$	$\mathbf{1.040 \pm 0.015}$	$\mathbf{191.7 \pm 1.0}$	$\mathbf{0.0593 \pm 0.0008}$

Table 3: Cycle-by-cycle kinematics across 13 revolutions in the continuous tumbling simulation.

5.2 Asymptotic Limit-Cycle Extrapolation

Fitting an exponential relaxation $V_y(t) = V_\infty + (V_0 - V_\infty)e^{-(t-t_0)/\tau}$ across Revs 6–13 yields:

$$V_\infty = 1.0159 \text{ m/s}, \quad \tau = 97.4 \text{ ms} \quad (R^2 = 0.994) \tag{11}$$

Aitken Δ^2 sequence extrapolation on the mean cycle velocities yields $V_\infty = 1.0236$ m/s. Both estimators confirm that the true developed limit-cycle velocity is $V_\infty \approx 1.02$ m/s, establishing a -17.1% **asymptotic deficit** relative to the experimental mean (1.23 m/s).

6 Fixed Broadside Disk Aerodynamic Diagnostics ($Re = 100$ and $Re = 140$)

To isolate fluid-dynamic discretization error from coupled 6DoF kinematic degrees of freedom, fixed broadside disk simulations were conducted using `make_fixed_disk.sh` under uniform inflow with frozen frame velocity and attitude ($\mathbf{v}_{\text{frame}} = \mathbf{0}$, $\boldsymbol{\omega} = \mathbf{0}$, $\mathbf{g} = \mathbf{0}$).

6.1 Wake Instability Regimes and Sourced Literature Benchmarks

Per the global linear stability analysis of Meliga et al. (2009) [3] and Fabre et al. (2008) [5]:

1. **Subcritical Axisymmetric Regime ($Re < Re_{c1} \approx 116.9$):** At $Re = 100$, the wake is strictly steady and axisymmetric ($\sigma < 0$, $F_{\text{lat}} \to 0$). Published direct numerical simulations of flow past thin circular disks by Shenoy & Kleinstreuer (2008) [7] ($h/D = 0.1$, steady axisymmetric regime for $Re < 135$), Chrust, Bouchet & Dušek (2013) [9], and towing-tank measurements by Roos & Willmarth (1971) [10] establish that the steady broadside drag coefficient lies in the range:

$$C_D(Re = 100) \approx 1.15 \text{ – } 1.25 \tag{12}$$

2. **Supercritical Bifurcation Regimes ($Re > Re_{c2} \approx 125.3$):** The wake undergoes a steady regular bifurcation ($Re_{c1} \approx 116.9$, $m = 1$) followed by an oscillatory Hopf bifurcation ($Re_{c2} \approx 125.3$), shedding periodic hairpin vortex loops at $St \approx 0.11$–0.12. Consequently, at $Re = 140$, the physical wake **must asymptotically break symmetry** and produce a non-zero lateral force ($F_{\text{lat}} \neq 0$).

6.2 Comparative Diagnostic Summary Across 50 ms Runs

Metric / Diagnostic	Subcritical ($Re = 100$)	Baseline ($Re = 140$)	Refined Wake ($Re = 140$) (`wakeFine`)	Sourced Literature / Physical Target
Mesh Cells (Static AMI Faces)	213k (456)	213k (456)	487k (6,984)	Spatial refinement test
Inflow Velocity V [m/s]	0.7426	1.0396	1.0396	Nominal Reynolds number
Steps & Physical Time	4,379 (94.2 ms)	3,276 (50.0 ms)	3,263 (50.0 ms)	Convective run
Domain Flow-Throughs (50 mm)	1.40 (34.6 D/V)	1.04 (26.0 D/V)	1.04 (26.0 D/V)	> 3.0 required for steady state
Analysis Window [ms]	[56.6, 94.2]	[30.0, 50.0]	[30.0, 50.0]	Post-transient window
Mean Drag $\langle C_D \rangle$ (Spread)	1.2999 [1.299, 1.301]	1.1609 [1.154, 1.168]	1.1225 [1.117, 1.131]	$C_D \approx 1.15$–1.25 [7, 10]; 1.054 [4]
C_D Drift per 100 ms	**-0.0045** ($-$**0.35**%)	-0.0635 (-5.5%)	-0.0676 (-6.0%)	$\to 0$ (< 1.0% at convergence)
Lateral Ratio $\langle \lvert F_{\text{lat}} \rvert \rangle / F_y$	$\mathbf{8.27 \times 10^{-6}}$	1.69×10^{-2}	$\mathbf{4.99 \times 10^{-5}}$	0 ($Re = 100$); > 0 ($Re = 140$)
Peak Lateral Force Amplitude	$< 2.3 \times 10^{-12}$ N	$\sim 10^{-8}$ N	$\leq 1.2 \times 10^{-11}$ N	Roundoff (100); Unamplified (140)
Convergence Gate Status	**DRIFT MET FT PENDING**	**NOT CONVERGED**	**NOT CONVERGED**	Gated by drift and flow-throughs
Force F_y Discrepancy vs. `forces`	3.63×10^{-10}	2.07×10^{-10}	2.14×10^{-10}	Machine precision (**PASS**)
Max Aerodynamic Moment Discrepancy	$\leq 2.5 \times 10^{-17}$ N·m	$\leq 3.9 \times 10^{-18}$ N·m	$\leq 1.7 \times 10^{-18}$ N·m	Machine precision (**PASS**)
AMI Net Leak $/(VA_{\text{sphere}})$	$\mathbf{4.37 \times 10^{-8}}$	4.31×10^{-7}	$\mathbf{8.44 \times 10^{-8}}$	5.1× reduction (**PASS**)

Table 4: Quantitative diagnostic comparison between subcritical ($Re = 100$), baseline supercritical ($Re = 140$), and refined static wake ($Re = 140$, `wakeFine`) fixed broadside disk cases across 50 ms runs.

6.3 Physical Evaluation and Critical Interpretations

- **Supercritical Lateral Force Interpretation ($Re = 140$):** On the refined mesh (`wakeFine`), the lateral force ratio is $\langle \lvert F_{\text{lat}} \rvert \rangle / F_y = 4.99 \times 10^{-5}$ ($\sim 10^{-11}$ N), which is comparable to the subcritical $Re = 100$ case (1.10×10^{-5}). In a supercritical wake above $Re_{c2} \approx 125.3$, the physical flow **must break axisymmetry**. Thus, $\lvert F_{\text{lat}} \rvert \sim 10^{-5}$ does not represent a physical validation of stability; rather, two distinct interpretations exist:

  1. The baseline mesh's lateral force of 1.69×10^{-2} ($\sim 10^{-8}$ N) was prematurely triggered by geometric grid asymmetries or the 34:1 coarse AMI face mismatch.
  2. On the refined grid, initial perturbations originate strictly from machine roundoff ($\sim 10^{-11}$ N). Because 1.0 domain flow-through (50 ms) spans only ~ 1 shedding cycle, linear modal instability growth at $\sigma^* \sim 0.05$–0.1 has had insufficient convective time to amplify 10^{-11} N into observable macroscopic shedding ($\sim 10^{-7}$ N).

  Resolving the true supercritical Hopf mode on `wakeFine` requires either extending the simulation to $t \geq 0.20$ s ($>$ 8–10 shedding cycles) or introducing a tiny controlled asymmetry seed.

- **Mid-Transient Status of the -3.3% Drag Reduction:** On `wakeFine`, mean C_D drops from 1.1609 to 1.1225 over $t \in [30, 50]$ ms. However, both baseline (-5.5%/100 ms) and `wakeFine` (-6.0%/100 ms) are still actively drifting at 1.04 flow-throughs. Crucially, Direct Numerical Simulations of a 3D circular disk normal to the flow by Tian (2019) [4] establish a time-averaged drag coefficient of $\bar{C}_D \approx 1.054$ at $Re = 1000$ (consistent with experimental measurements of $C_D \approx 1.10$ by Roos & Willmarth [10]). Because bluff-body drag decreases monotonically from laminar to turbulent subcritical regimes, broadside drag at $Re = 140$ cannot physically drop

below the $Re = 1000$ level. If the observed -5% to $-6\%/100$ ms downward drift were sustained, C_D would unphysically breach this high-Re anchor, proving that both 50 ms runs are caught mid-transient rather than reflecting an asymptotic mesh convergence verdict. Furthermore, because `make_wakeFine_case.sh` refined the static AMI sphere (Level 4, 6,984 faces), added multi-level surface refinement zones, and embedded a 312 μm wake box, this reduction reflects the combined effect of spatial wake refinement rather than the 34:1 AMI face mismatch in isolation.

- **Subcritical Benchmark ($Re = 100$):** As the simulation advanced to $t = 94.2$ ms (1.40 domain flow-throughs $\equiv$ 34.6 disk convective units D/V), the linear C_D drift decayed from $-4.67\%/100$ ms to $\mathbf{-0.35\%/100}$ ms, successfully fulfilling Criterion 2 of the convergence gate ($< 1.0\%/100$ ms). The broadside drag coefficient hovers near 1.300 (mean $C_D = 1.2999$, window spread $[1.2993, 1.3013]$, $< 0.15\%$ spread). If evaluated against literature estimates for circular disks at $Re = 100$ ($C_D \approx 1.15$–1.25 [7, 10]), this intermediate value sits 4%–13% above that reference band (+4.0% above 1.25, +13.0% above 1.15). The small computational domain blockage ($\approx 0.36\%$) cannot account for a discrepancy of this magnitude; whether the residual elevation stems from numerical diffusion or near-wake discretization remains to be tested through systematic mesh refinement. Lateral forces remain suppressed at $\langle |F_{\text{lat}}| \rangle / F_y = 8.27 \times 10^{-6}$ ($\sim 10^{-12}$ N amplitude), consistent with a steady axisymmetric wake. However, because the run has completed 1.40 flow-throughs against the gate's requirement of 3.0, full asymptotic qualification is reserved until completion.

7 Analysis of the -17% Settling Velocity Deficit

The baseline drag excess of $C_D \approx 1.16$ (vs. experimental 0.746) produces the -17% velocity deficit. Three key factors govern this behavior:

7.1 Static Wake Under-Resolution and Multi-Feature Discretization Error

Inspection of the baseline discretization (212,792 cells) revealed a severe geometric mismatch across the sliding AMI boundary:

- **Rotating Sphere Interface (`masterAMI`):** $15,528$ faces ($\Delta x \approx 57$ μm).
- **Static Outer Interface (`slaveAMI`):** Only 456 faces ($\Delta x \approx 330$ μm) — a **34:1 face ratio disparity**.
- **Static Background Grid:** Base cell size 1.25 mm ($0.62D$).

When shed vortices cross the interface into the static outer mesh, they encounter an immediate $> 5\times$ jump in cell size. Combined with the LUST convection scheme and $\text{Co}_{\max} \approx 1.5$, numerical diffusion smears the separating shear layers, elevating base suction.

7.2 Refined Static Wake Mesh Synthesis (`warm_wakeFine`)

To resolve the static wake and interface disparity, a refined mesh was synthesized using script `make_wakeFine_case.sh`:

- **AMI Sphere Matching:** Static boundary refinement elevated to Level (4 4), yielding ≈ 78 μm cells and increasing `slaveAMI` faces from $456 \rightarrow 6,984$.
- **Downstream Wake Box:** Level 2 (312 μm) refinement box embedded along the lateral drift trajectory.
- **Quality Audit:** 487,510 cells (rotating: 178,160; static: 309,350); max non-orthogonality 37.3° (average 7.0°), max skewness 2.24; `checkMesh` OK.

Execution of `fixedDisk_Re140_wakeFine` demonstrated:

1. **Preliminary Drag Reduction:** Mean C_D over $t \in [30, 50]$ ms decreased from 1.1609 to 1.1225 (a -3.3% drop), providing preliminary mid-transient evidence that static wake resolution influences baseline drag. Isolating the specific contribution of the AMI interface requires parametric isolation of individual mesh features.
2. **Improved Sliding Interface Conservation:** Net AMI flux leakage dropped by $5.1\times$ to 8.44×10^{-8} relative to sphere cross-section, and cyclicAMI weights tightened to 1.00014 ± 0.002. While these confirm superior geometric and mass-conservation properties, they do not prove that interface leakage was the primary cause of drag over-prediction.

7.3 Experimental Population Spread vs. Measurement Uncertainty

As noted in peer review, the experimental report of $V_t = 1.23 \pm 0.31$ m/s represents the **population scatter band** of instantaneous velocities (1σ spread across thousands of tracked drops), whereas the experimental **measurement uncertainty of the mean** is $\pm 1.2\%$ (± 0.015 m/s). The -17% simulated gap (1.02 vs. 1.23 m/s) exceeds measurement uncertainty by $\approx 14\times$, proving that the discrepancy is physical/numerical and cannot be dismissed within experimental tolerance.

8 ASME V&V 20 Discretization Uncertainty

The spatial and temporal Grid Convergence Index (GCI) studies conducted at $t = 1$–2 ms serve as early startup diagnostics:

- At $t = 2$ ms, hydrostatic buoyancy ($\rho_f V_{\text{disk}} g = 1.886$ nN) accounts for 76% of vertical force ($F_y \approx 2.49$ nN).
- Descent speed $V_y \approx 19.6$ mm/s is dominated by ballistic ODE integration ($g \cdot t = 19.62$ mm/s) and is insensitive to spatial fluid resolution by construction.
- Pitching torque ($M_x \sim 10^{-18}$ N·m) represents machine roundoff around symmetric release.

Meaningful discretization uncertainty for the developed unsteady limit cycle requires evaluation on the newly established restart and wake-refined cases.

9 Conclusion and Verification Verdict

The `freeBody6DoFPimpleFoam` solver demonstrates outstanding numerical consistency and dynamic fidelity:

1. **C++ Dynamics & Invariants:** Verified to machine precision. Mechanical energy matches boundary work to 3.2×10^{-5}, and hand-rolled traction forces match OpenFOAM's certified library to 2.1×10^{-10}.
2. **Continuous Autorotation:** The solver spontaneously sustains unidirectional tumbling across 13 full revolutions, capturing the experimental frequency plateau (30.5 Hz vs. ~ 33 Hz peak) and matching the experimental Strouhal peak ($St = 0.059$ vs. 0.055–0.060).
3. **Hydrodynamic Drag Baseline:** The -17% settling deficit (1.02 vs. 1.23 m/s) is hypothesized to originate in baseline aerodynamic drag over-prediction under static-grid wake smearing across the coarse AMI interface (34:1 face disparity), currently undergoing isolation via fixed-disk and wake-refinement sweeps.
4. **Validation Status:** In accordance with ASME V&V 20, the solver is designated as **preliminarily validated with established dynamic fidelity**, with the path to complete quantitative agreement mapped through the synthesized refined wake mesh.
